Differential Privacy in the Shuffle Model: A Survey of Separations

Albert Cheu

July 16, 2021

1 Introduction

Many differentially private algorithms operate in the *central model*, also known as the trusted curator model. Here, a single analyzer has raw user data and its computations are insensitive to any one user's data point. But the fact that all users give their data to one party means that there is a single point of failure: the privacy of all users is contingent on the integrity of the analyzer.

There are a number of ways to model weaker trust in the analyzer, chief among them being the *local model*. Here, the dataset is a distributed object where each user holds a single element. To preserve their own privacy, each user executes a randomizing function on their data point and submits the resulting outputs to the analyzer. Because the signal from each user is hidden behind noise, there are a number of lower bounds on the error of locally private protocols that strongly separate the local model from the central model [14, 17, 11, 1, 38]. That is, the analyzer needs more samples (users) to achieve the same accuracy as in the central model. Locally private protocols are also more vulnerable to manipulation: by sending carefully distributed messages, malicious users can skew tests and estimates of distributions beyond simply changing the input of the protocol [21]. These negative results lead us to ask the following question:

> Can we achieve the accuracy that is possible with centrally private algorithms from a trust assumption that is close to locally private protocols?

Research into the *shuffle model* has given an answer to this question. Like the local model, users in a shuffle protocol produce messages by feeding their data into a local randomizer. But now they trust some entity to apply a uniformly random permutation on all user messages. We assume that the adversary's view is limited to that permutation, so no message can be linked back to its sender.

This survey gives an overview of the recent surge of work in the shuffle model. We pay particular attention to results that characterize the strength of the model relative to the local and central models.

Outline. We first establish the requisite privacy and model definitions. Next we contrast local model lower bounds with shuffle model upper bounds: there are problems for which additive error and sample complexity are much lower in the shuffle model. Then we give techniques to show that the shuffle model (under natural constraints) is weaker than the central model. Finally, we discuss what is possible in interactive variants of the model.

All these results focus on the accuracy of shuffle privacy. In Appendix A, we give an overview of protocols that are designed with the aim of reducing the cost of transmission.

2 Preliminaries

We will use the notation $[k] = \{1, 2, \ldots, k\}$, $\mathbb{N} = \{1, 2, \ldots\}$. A dataset $\vec{x} \in \mathcal{X}^n$ is an ordered tuple of n rows where each row is drawn from a data universe $\mathcal{X}$ and corresponds to the data of one user. Two datasets $\vec{x}, \vec{x}' \in \mathcal{X}^n$ are considered *neighbors* if they differ in at most one row. This is denoted as $\vec{x} \sim \vec{x}'$.

Definition 1 (Differential Privacy [26])**.** An algorithm $\mathcal{M} : \mathcal{X}^n \to \mathcal{Z}$ satisfies (ε, δ)-*differential privacy* if, for every pair of neighboring datasets $\vec{x}$ and $\vec{x'}$ and every subset $T \subset \mathcal{Z}$,

$$\mathbb{P}\left[\mathcal{M}(\vec{x}) \in T\right] \leq e^{\varepsilon} \cdot \mathbb{P}\left[\mathcal{M}(\vec{x}') \in T\right] + \delta.$$

When $\delta > 0$, we say $\mathcal{M}$ satisfies *approximate* differential privacy. When $\delta = 0$, $\mathcal{M}$ satisfies *pure* differential privacy and we omit the δ parameter.

Because this definition assumes that the algorithm $\mathcal{M}$ has "central" access to compute on the entire raw dataset, we sometimes call this *central* differential privacy.

One useful centrally private algorithm is the *binomial mechanism*.

Lemma 2 (Binomial Mechanism [25, 32])**.** *Let $f : \mathcal{X}^n \to \mathbb{Z}$ be a 1-sensitive function, i.e. $|f(\vec{x}) - f(\vec{x}')| \leq 1$ for all neighboring datasets $\vec{x}, \vec{x}' \in \mathcal{X}^n$. There is a constant κ such that, for any $\ell \in \mathbb{N}$, $p \in (0, 1)$, and $\varepsilon, \delta \in (0, 1)$ satisfying*

$$\ell \cdot \min(p, 1 - p) \geq \frac{\kappa}{\varepsilon^2} \cdot \log \frac{1}{\delta},$$

the algorithm that samples $\eta \sim \mathbf{Bin}(\ell, p)$ and outputs $f(\vec{x}) + \eta$ is (ε, δ)-differentially private. The error is $O\left(\frac{1}{\varepsilon}\sqrt{\log \frac{1}{\delta}}\right)$ with constant probability.

2.1 The Local Model

We first establish the local model. Here, the dataset is a distributed object where each of n users holds a single row. Each user i provides their data point as input to a randomizing function $\mathcal{R}$ and publishes the outputs for some analyzer to compute on.

Definition 3 (Local Model [43, 29])**.** A protocol $\mathcal{P}$ in the *local model* consists of two randomized algorithms:

- A randomizer $\mathcal{R} : \mathcal{X} \times \{0, 1\}^r \to \mathcal{Y}$ mapping a data point and public random bits to a message
- An analyzer $\mathcal{A} : \mathcal{Y}^n \times \{0, 1\}^r \to \mathcal{Z}$ that computes on a vector of messages and public random bits

We define its execution on input $\vec{x} \in \mathcal{X}^n$ as

$$\mathcal{P}(\vec{x}) := \mathcal{A}(\mathcal{R}(x_1, W), \ldots, \mathcal{R}(x_n, W)),$$

where W is a uniformly random member of $\{0, 1\}^r$. We assume that $\mathcal{R}$ and $\mathcal{A}$ have access to n.

Remark 4. *It is possible to extend the model definition to allow for multiple rounds of communication. To ease readability, we defer discussion of interactive protocols (local and shuffle) to a later section.*

Suppose the privacy adversary wishes to target user i. In this model, the adversary's view is limited to the output of $\mathcal{R}(x_i, W)$ so we impose the privacy constraint on $\mathcal{R}$.

Definition 5 (Local Differential Privacy [26, 39])**.** A protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ is (ε, δ)-*local differentially private* if, for all $w \in \{0, 1\}^r$, $\mathcal{R}(\cdot, w)$ is (ε, δ)-differentially private. That is, the privacy guarantee is over the internal randomness of the users' randomizers and not the public randomness of the protocol.

2.2 The Shuffle Model

To give intuition for the shuffle model, we start by sketching a preliminary version called the *single-message shuffle model*. Like the (one-round) local model, users execute $\mathcal{R}$ on their data to produce messages but users now trust a service to perform a secure shuffle on the messages. That is, an adversary's view is limited to a uniformly random permutation of the messages, so no message can be linked back to its sender. Intuitively, whatever privacy guarantee is granted by $\mathcal{R}$ is *amplified* by this anonymity: to learn about x_i, an adversary has to not only recover information from one noisy message y_i but somehow identify the target message inside a vector $\vec{y}$ of n messages. Amplification-by-shuffling lemmas quantify how well the privacy parameters are improved [28, 10, 30]. Though these lemmas provide a simple way to design single-message shuffle protocols, this survey will only occasionally mention them.

This is because we will focus on the generalization where each user can send any number of messages to the shuffler. The shuffling prevents messages from the same sender from being linked with one another. The design and analysis of these protocols are not captured by amplification results.

Definition 6 (Shuffle Model [15, 22])**.** A protocol $\mathcal{P}$ in the *shuffle model* consists of three randomized algorithms:

- A *randomizer* $\mathcal{R} : \mathcal{X} \times \{0,1\}^r \to \mathcal{Y}^*$ mapping a data point and public random bits to (possibly variable-length) vectors. The length of the vector is the number of messages sent. If, on all inputs, the probability of sending m messages is 1, then we have an *m-message protocol*.
- A *shuffler* $\mathcal{S} : \mathcal{Y}^* \to \mathcal{Y}^*$ that concatenates message vectors and then applies a uniformly random permutation to the messages.
- An *analyzer* $\mathcal{A} : \mathcal{Y}^* \times \{0,1\}^r \to \mathcal{Z}$ that computes on a permutation of messages and public random bits.

As $\mathcal{S}$ is the same in every protocol, we identify each shuffle protocol by $\mathcal{P} = (\mathcal{R}, \mathcal{A})$. We define its execution on input $\vec{x} \in \mathcal{X}^n$ as

$$\mathcal{P}(\vec{x}) := \mathcal{A}(\mathcal{S}(R(x_1, W), \ldots, R(x_n, W))),$$

where W is again the public random string. We assume that $\mathcal{R}$ and $\mathcal{A}$ have access to n.

As with the local model, we can generalize the shuffle model to allow for interactive protocols. We defer the definitions to a later section.

With this setup, we use the following definition of shuffle differential privacy.

Definition 7 (Shuffle Differential Privacy [22])**.** A protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ is (ε, δ)-*shuffle differentially private* if, for all $n \in \mathbb{N}$ and $w \in \{0,1\}^r$, the algorithm $(\mathcal{S} \circ \mathcal{R}^n)(\vec{x}) := \mathcal{S}(\mathcal{R}(x_1, w), \ldots, \mathcal{R}(x_n, w))$ is (ε, δ)-differentially private.

For brevity, we typically call these protocols "shuffle private." We will also drop the public randomness input if it is unused.

Note that Definition 7 assumes all users follow the protocol. But malicious users could aim to make the protocol less private; ideally, the parameters should degrade smoothly with the number of such malicious users. A simple attack is to drop out: for $\gamma \leq 1$, let $\mathcal{S} \circ \mathcal{R}^{\gamma n}$ denote the case where only γn out of n users execute $\mathcal{R}$. Because the behavior of the randomizer may depend on n, $\mathcal{S} \circ \mathcal{R}^n$ may satisfy a particular level of differential privacy but $\mathcal{S} \circ \mathcal{R}^{\gamma n}$ may not.[1] This motivates a *robust* variant of shuffle privacy.

[1] Note that, with respect to differential privacy, dropping out is "the worst" malicious users can do. This is because adding messages from malicious users to those from honest users is a post-processing of $\mathcal{S} \circ \mathcal{R}^{\gamma n}$. If $\mathcal{S} \circ \mathcal{R}^{\gamma n}$ is already differentially private for the outputs of the γn users alone, then differential privacy's resilience to post-processing ensures that adding other messages does not affect this guarantee. Hence, it is without loss of generality to focus on drop-out attacks.

Definition 8 (Robust Shuffle Differential Privacy [7, 19])**.** Fix continuous and non-increasing functions $\tilde{\varepsilon}, \tilde{\delta}$ such that $0 < \tilde{\varepsilon}(\gamma) < \infty$ and $0 < \tilde{\delta}(\gamma) < 1$ for all $\gamma \in [1/2, 1]$. A shuffle protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ is $(\tilde{\varepsilon}, \tilde{\delta})$-*robustly differentially private for n users* if, for all $\gamma \in [1/2, 1]$ such that $\gamma n \in \mathbb{N}$, the algorithm $\mathcal{S} \circ \mathcal{R}^{\gamma n}$ is $(\tilde{\varepsilon}(\gamma), \tilde{\delta}(\gamma))$-differentially private.

As with generic shuffle differential privacy, we often shorthand this as "robust shuffle privacy." We remark that the value 1/2 above could instead be a threshold parameter τ but we avoid this to simplify the presentation. That is, it can be changed to some other constant like 1/3 and the robustly shuffle private protocols in this survey would still satisfy the definition.

Note that we define robustness with regard to privacy rather than accuracy. A robustly shuffle private protocol promises its users that their privacy will not suffer much from a limited fraction of malicious users. But it does not make any guarantees about the accuracy of the protocol; we will state our accuracy guarantees under the assumption that all users follow the protocol.

We emphasize that robustness is not immediately implied by the basic form of shuffle privacy in Definition 7. Appendix B describes protocols that satisfy shuffle privacy but are not robust to drop-outs.

3 Separations between Local & Shuffle Privacy

In this section, we will introduce four problems. For each problem, we will state a lower bound in the local model and then describe a protocol in the shuffle model that breaks through that bound. To simplify the presentation, we will assume $\varepsilon < 1$ and $\delta = O(1/\text{poly}(n))$.

3.1 Binary Sums

In this setting, each user i has a bit $x_i \in \{0, 1\}$ and the objective is to compute the sum (count privately). Dating back to Warner [43], *randomized response* is the canonical local protocol for this problem. The randomizer is below:

$$\mathcal{R}_{\mathsf{RR}}(x_i) := \begin{cases} \textbf{Ber}(1/2) & \text{with probability } p \\ x_i & \text{otherwise} \end{cases}$$

Let y_i be the message sent by user i. Due to subsampling and noise addition, the expected value of $\sum y_i$ is $(1-p) \cdot \sum x_i + np/2$. The analyzer will re-center and re-scale to obtain an unbiased estimator:

$$\begin{aligned} \mathcal{A}_{\mathsf{RR}}(\vec{y}) &:= \frac{1}{1-p}\left(\sum y_i - np/2\right) \\ \mathbb{E}\left[\mathcal{A}_{\mathsf{RR}}(\vec{y})\right] &= \frac{1}{1-p} \cdot \left(\mathbb{E}\left[\sum y_i\right] - np/2\right) \\ &= \sum x_i \end{aligned}$$

Setting $p \leftarrow 2/(e^{\varepsilon} + 1)$ suffices for ε-local privacy but incurs an additive error of $O(\frac{1}{\varepsilon}\sqrt{n})$. This is optimal.

Theorem 9 (Beimel et al. [14] & Chan et al. [17])**.** *Let $\mathcal{P}$ be an (ε, δ)-locally private protocol. If $\mathcal{P}$ computes binary sums up to additive error α with constant probability, then $\alpha = \Omega(\frac{1}{\varepsilon}\sqrt{n})$.*

Note that $\mathcal{P}_{\mathsf{RR}} := (\mathcal{R}_{\mathsf{RR}}, \mathcal{A}_{\mathsf{RR}})$ can also be interpreted as a single-message shuffle protocol. Cheu et al. [22] show that the parameter p can be chosen such that RR achieves robust shuffle privacy while also avoiding error that scales polynomially with n.

Theorem 10 (Cheu et al. [22])**.** *There exists a choice of p such that randomized response $\mathcal{P}_{\mathsf{RR}} = (\mathcal{R}_{\mathsf{RR}}, \mathcal{A}_{\mathsf{RR}})$ is $(\varepsilon/\sqrt{\gamma}, \delta)$-robustly shuffle private and computes binary sums up to additive error $O(\frac{1}{\varepsilon}\sqrt{\log \frac{1}{\delta}})$ with constant probability.*

Proof. We will set p to a value $\Omega(\frac{1}{\varepsilon^2 n}\log\frac{1}{\delta})$. If this quantity exceeds 1/2 (which occurs when n is not large enough), p must take a different form and the analysis will naturally change; we omit this technicality for neatness. Refer to [22] for more details.

Robust privacy: Assume without loss of generality that the set of honest users is $[\gamma n]$. We leverage the fact that the view of an adversary is an unordered set of bits. This contains as much information as their sum. More formally, given $\sum_{i=1}^{\gamma n} y_i$, the adversary can simulate a sample from $\mathcal{S}(y_1,\ldots,y_{\gamma n})$: pick a uniformly random binary string of length γn and sum $\sum_{i=1}^{\gamma n} y_i$. Now we only have to ensure the privacy of $\sum_{i=1}^{\gamma n} y_i$.

By construction, some set of users $H \subset [\gamma n]$ will report messages sampled from $\mathbf{Ber}(1/2)$ and the rest will report their true values. So for any fixed set H, $\sum_{i=1}^{\gamma n} y_i$ is a sample from $\sum_{i\in[\gamma n]-H} x_i + \mathbf{Bin}(|H|, 1/2)$. We can invoke privacy of the binomial mechanism once we show $|H| \geq \frac{2\kappa\gamma}{\varepsilon^2}\cdot\log\frac{1}{\delta}$, where κ is the constant in Lemma 2.

Membership in H is a Bernoulli process, so $|H| \sim \mathbf{Bin}(\gamma n, p)$. Due to our choice of p, standard concentration arguments imply $|H| \geq \frac{2\kappa\gamma}{\varepsilon^2}\cdot\log\frac{1}{\delta}$ with at least $1-\delta$ probability.

Accuracy: We bound the protocol's error under the assumption that all users are honest ($\gamma = 1$). Recall that the output of the protocol is $\frac{1}{1-p}(\sum y_i - np/2)$. By a Chernoff bound, we have that $\sum y_i - np/2$ is within $O(\frac{1}{\varepsilon}\sqrt{\log\frac{1}{\delta}})$ of its expectation. And because $\frac{1}{1-p} < 2$, the error of the unbiased estimator is $O(\frac{1}{\varepsilon}\sqrt{\log\frac{1}{\delta}})$. □

We remark that there are other shuffle protocols for binary sums with low error; Table 1 presents their most salient features.

Table 1: Shuffle protocols for binary sums. Each message is one bit. "$*$" denotes a bound that holds in expectation over the randomness of all users.

Given name	Error	No. Messages per User	Advantage over RR	Source
RR	$O(\frac{1}{\varepsilon}\cdot\sqrt{\log\frac{1}{\delta}})$	1	—	[22]
ZSUM	$O(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$	2	If sum is 0, estimate is 0	[6]
—	$O(\frac{1}{\varepsilon^{3/2}}\cdot\sqrt{\log\frac{1}{\varepsilon}})$	$O(\frac{1}{\varepsilon}\log n)$	$\delta = 0$	[31]
—	$O(\frac{1}{\varepsilon}\cdot\sqrt{\log\frac{1}{\delta}})$	$O(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})*$	Noise symmetry	[7]
—	$O(\frac{1}{\varepsilon})$	$1 + O(\frac{1}{\varepsilon^2 n}\log^2\frac{1}{\delta})*$	Optimal error	[33]

The Noise/Data Dichotomy. In randomized response, a message can either be a Bernoulli bit or a data bit. A common design pattern in the alternative protocols is to send these types separately. That is, a user transmits multiple messages where one message is their data bit and the remaining messages are random bits. This has the effect of avoiding the re-scaling done in $\mathcal{A}_{\mathsf{RR}}$ to compensate for subsampling.

Balle, Bell, Gascón, and Nissim [10] prove the following: any locally private randomizer (not just $\mathcal{R}_{\mathsf{RR}}$) can be expressed as a mixture of noise and data. Specifically, there is a "blanket" distribution $\mathbf{B}$ and a parameter p such that, for any input x, the distribution of $\mathcal{R}(x)$ is equal to $p\mathbf{B}+(1-p)\mathbf{D}_x$ where $\mathbf{D}_x$ an input-dependent distribution (identity in the case of $\mathcal{R}_{\mathsf{RR}}$). [10] use this to prove their amplification-by-shuffling lemma.

Given a protocol for binary sums like $\mathcal{P}_{\mathsf{RR}}$, we can solve a host of other problems. One of these is bounded value sums: user data now take any value in $[0,1]$. To keep the focus on the separation between local and robust shuffle privacy, we will defer discussion of bounded-value sums to Appendix A.

3.2 Histograms

In this setting, each user has one value in the set $[k]$. Let c_j denote the count of j in the input dataset. The objective is to privately compute a vector $(\tilde{c}_1, \ldots, \tilde{c}_k)$ such that the ℓ_∞ distance from $(c_1, \ldots, c_k)$ is small. In other words, the output's maximum error should be low. This error must grow with k under local privacy:

Theorem 11 (Bassily & Smith [11])**.** *Let $\mathcal{P}$ be an (ε, δ)-locally private protocol. If $\mathcal{P}$ reports a histogram that has ℓ_∞ error α with constant probability, then $\alpha = \Omega(\frac{1}{\varepsilon}\sqrt{n \log k})$*

In contrast, it is possible to have error independent of k under robust shuffle privacy:

Theorem 12 (Balcer et al. [6, 7])**.** *There is a histogram protocol that satisfies $(2 \cdot \varepsilon/\sqrt{\gamma}, 2\delta)$-robust shuffle privacy for any $\gamma \in (0,1]$. Its estimate has ℓ_∞ error $O(\frac{1}{\varepsilon^2} \log \frac{1}{\delta})$ with constant probability.*

Proof. A simple way to obtain a private histogram is to privately count each of the k elements. A union bound suffices to upper bound the maximum magnitude of error. Basic composition ensures that we only pay a factor of 2 in the privacy parameters, since changing a user's value from x to x' only affects the counts of the two values x and x'.

In the shuffle model, the k protocol executions can be done in parallel: each user label their messages. To be precise, let $\mathcal{R}_j$ be a binary sum randomizer that counts the occurrences of j. If $\mathcal{R}_j(x_i)$ outputs messages a and b, user i reports the tuples (j, a) and (j, b). To estimate c_j, we can feed the messages into the corresponding analyzer function $\mathcal{A}_j$.

A side-effect of this reduction approach is that the union bound may create a dependence on k. For example, if we use RR for frequency estimation, the ℓ_∞ error after the union bound has a $\sqrt{\log k}$ term. But we can avoid this dependence by using ZSUM, a binary sum protocol which guarantees noiseless estimation when the input is $(0, \ldots, 0)$. As such, the elements with nonzero frequency will be the only ones with noisy estimates. But there are only $\leq n$ of these, so the union bound is over $\leq n$ protocol executions instead of k.

We present the local randomizer of ZSUM below. r is a parameter to be determined.

$$\mathcal{R}_{\mathsf{ZSUM}}(x_i) := (x_i, \mathbf{Ber}(r))$$

Robust Privacy: As with RR, it suffices to prove privacy of the sum of the messages from honest users. But this quantity is exactly $\sum_{i=1}^{\gamma n} x_i + \eta$, where η is drawn from the distribution $\mathbf{Bin}(\gamma n, r)$. And by Lemma 2, it suffices to choose $r = 1 - \frac{\kappa}{\varepsilon^2 n} \cdot \log \frac{1}{\delta}$ for $(O(\varepsilon/\sqrt{\gamma}), \delta)$ privacy.[2]

Accuracy: Now we define the analyzer $\mathcal{A}_{\mathsf{ZSUM}}$.

$$\mathcal{A}_{\mathsf{ZSUM}}(\vec{y}) := \begin{cases} 0 & \text{if } \sum y_{i,1} + y_{i,2} \leq n \\ \sum y_{i,1} + y_{i,2} - nr & \text{otherwise} \end{cases}$$

First consider the case where $\sum x_i = 0$. Because $\eta \sim \mathbf{Bin}(n, r)$ has maximum value n, $\mathbb{P}\left[\sum y_{i,1} + y_{i,2} \leq n\right] = 1$ so there is zero error.

Now consider the case where $\sum x_i = 0$. We can use a Chernoff bound to argue that $|\eta - nr| = O(\sqrt{n(1-r)\log n})$ with probability $1/10n$. If we do not truncate, subtracting nr removes bias so that

[2] If $n < \frac{2\kappa}{\varepsilon^2} \cdot \log \frac{1}{\delta}$, notice that $r > 1/2$. In this case, honest users can simply opt to report (0,0). Perfect privacy is achieved at the price of error $n = O(\frac{1}{\varepsilon^2} \cdot \log \frac{1}{\delta})$

error has magnitude $O(\sqrt{n(1-r)\log n}) = O(\frac{1}{\varepsilon}\log\frac{1}{\delta})$. Otherwise, error is exactly $\sum x_i$. But truncation will not occur when $\sum x_i = \Omega(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$: in this case, $\sum x_i + \eta > \sum x_i + n - O(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$ so that $\sum y_{i,1} + y_{i,2} > n$. □

We remark that the number of messages per user can be changed to $O(n \cdot k^{1/T})$ for an arbitrary integer constant $T > 1$ at the price of inflating the error by a factor of $\approx T^2$. We flesh out this argument in the Appendix.

3.3 Uniformity testing

In *α-uniformity testing*, we assume each user has one i.i.d. sample from some probability distribution $\mathbf{D}$ over $[k]$. The objective is to report "uniform" with probability 2/3 when $\mathbf{D} = \mathbf{U}$ and "not uniform" with probability 2/3 when $\|\mathbf{D} - \mathbf{U}\|_{\mathrm{TV}} > \alpha$. The minimum number of users needed to ensure those two conditions hold is the *sample complexity* of the protocol. Under local privacy, this must scale at least linearly with k.

Theorem 13 (Acharya et al. [1])**.** *If an ε-locally private protocol performs α-uniformity testing, then its sample complexity is $\Omega(k/\alpha^2\varepsilon^2)$.*

But under robust shuffle privacy, it has been shown that the sample complexity is polynomially smaller. The result has two parts: a core testing protocol with sample complexity $O_{\alpha,\varepsilon,\delta}(k^{3/4})$ and then a domain compression lemma that lets us reduce the sample complexity to $O_{\alpha,\varepsilon,\delta}(k^{2/3})$.

Theorem 14 (Balcer et al. [7], Cheu [19])**.** *There is a multi-message protocol that satisfies $(2\cdot\varepsilon/\sqrt{\gamma}, 2\delta)$-robust shuffle privacy and solves α-uniformity testing with sample complexity*

$$O\left(\frac{k^{3/4}}{\alpha\varepsilon}\ln^{1/2}\left(\frac{1}{\delta}\right) + \frac{k^{2/3}}{\alpha^{4/3}\varepsilon^{2/3}}\ln^{1/3}\left(\frac{1}{\delta}\right) + \frac{k^{1/2}}{\alpha^2}\right).$$

Proof. We note that we will take $n \sim \mathbf{Pois}(m)$ and upper bound m. This "Poissonization" has the effect of making the random variables $c_1, \ldots, c_k$ mutually independent, which simplifies the analysis.

Cai et al. [16] give a recipe for private uniformity testing under Poissonization. First, compute a private histogram $(\tilde{c}_1, \ldots, \tilde{c}_k)$. Then, compute the test statistic

$$Z'(\tilde{c}_1, \ldots, \tilde{c}_k) := \frac{k}{m}\sum_{j=1}^{k}(\tilde{c}_j - m/k)^2 - \tilde{c}_j \tag{1}$$

The final step is to prove that this statistic is small when the data distribution is uniform but large when it is α-far from uniform, which means we can distinguish the two cases with a threshold test.

Amin et al. [5] give the following procedure to analyze Z'. If we let η_j be the noise in $\tilde{c}_j$ introduced by privacy, then we rewrite Z' as

$$\begin{aligned}(1) &= \frac{k}{m}\sum_{j=1}^{k}(c_j + \eta_j - m/k)^2 - c_j - \eta_j \\ &= \underbrace{\frac{k}{m}\sum_{j=1}^{k}(c_j - m/k)^2 - c_j}_{Z} + \underbrace{\frac{k}{m}\sum_{j=1}^{k}\eta_j^2}_{A} + \underbrace{\frac{2k}{m}\sum_{j=1}^{k}\eta_j\cdot(c_j - m/k)}_{B} - \underbrace{\frac{k}{m}\sum_{j=1}^{k}\eta_j}_{C}\end{aligned}$$

Analysis in Acharya et al. [3] imply bounds on term Z in the two relevant cases: there is a constant t and a function $f(\alpha, m)$ such that

1. when $\|\mathbf{D} - \mathbf{U}\|_{\mathrm{TV}} > \alpha$, $Z > t \cdot f(\alpha, m)$ with constant probability
2. when $\mathbf{D} = \mathbf{U}$, $Z \leq f(\alpha, m)$ with constant probability

If we prove the two statements below

(i) When $\|\mathbf{D} - \mathbf{U}\|_{\mathrm{TV}} > \alpha$, $A + B + C > 0$ with constant probability

(ii) When $\mathbf{D} = \mathbf{U}$, $A + B + C < (t-1) \cdot f(\alpha, m)$ with constant probability

then combining with 1. and 2. implies that the value $t \cdot f(\alpha, m)$ serves as a threshold that successfully separates the two cases with constant probability.

Balcer et al. [7] describe a binary sum protocol which produces estimates with zero-mean symmetric noise.[3] A corollary is that there is a private histogram protocol where each η_j is an independent sample from zero-mean symmetric noise. (i) immediately follows. (ii) follows from Chebyshev's inequality and the moments of η_j. □

We now sketch how to reduce the sample complexity dependence on k from $k^{3/4}$ to $k^{2/3}$. The technique is due to Acharya, Canonne, Han, Sun, and Tyagi [2] and Amin et al. [5] (itself a generalization of a similar technique from Acharya et al. [1]) The idea is to reduce the size of the data universe $[k]$ by grouping random elements and then performing the test on the smaller universe $[\hat{k}]$. The randomized grouping also reduces testing distance—partitions may group together elements with non-uniform mass to produce a group with near-uniform overall mass, thus hiding some of the original distance—but the reduction in universe size outweighs this side-effect.

Lemma 15 (Domain Compression [2, 5])**.** *Let $\mathbf{D}$ be a distribution over $[k]$. For any partition G of $[k]$ into $\hat{k} < k$ groups $G_1, \ldots, G_{\hat{k}}$, let $\mathbf{D}_G$ be the distribution over $[\hat{k}]$ with probability mass function $\mathbb{P}\left[\mathbf{D}_G = \hat{j}\right] := \sum_{j \in G_{\hat{j}}} \mathbb{P}[\mathbf{D} = j]$. If G is chosen uniformly at random, then with probability $\geq 1/954$ over G,*

$$\|\mathbf{D}_G - \mathbf{U}\|_{\mathrm{TV}} \geq \|\mathbf{D}_G - \mathbf{U}\|_{\mathrm{TV}} \cdot \frac{\sqrt{\hat{d}}}{477\sqrt{10k}}.$$

Public randomness can be used to create the partition G. Users can then replace their data j with the partition $\hat{j}$ it belongs to. Running the initial protocol the transformed dataset (with distance parameter $\hat{\alpha} := \alpha \frac{\sqrt{\hat{d}}}{477\sqrt{10k}}$) gives the final uniformity tester below:

Theorem 16 (Balcer et al. [7], Cheu [19])**.** *Fix any $\varepsilon = O(1)$, and $0 < \alpha, \delta < 1$. There exists a protocol that is $\left(2\varepsilon/\sqrt{\gamma}, 2\delta\right)$-robustly shuffle private and solves α-uniformity testing with sample complexity*

$$m = O\left(\left(\frac{k^{2/3}}{\alpha^{4/3}\varepsilon^{2/3}} + \frac{d^{1/2}}{\alpha\varepsilon} + \frac{k^{1/2}}{\alpha^2}\right) \cdot \ln^{1/2}\left(\frac{1}{\delta}\right)\right).$$

3.4 Pointer-Chasing

The *pointer chasing problem* is denoted $\mathrm{PC}(d, \ell)$ where $d, \ell \in \mathbb{N}$. A problem instance is a set $\{(1, \vec{a}), (2, \vec{b})\}$, where $\vec{a}$ and $\vec{b}$ are permutations of $[\ell]$. A protocol *solves* $\mathrm{PC}(d, \ell)$ *with sample complexity* n if, given n independent samples drawn uniformly with replacement from any problem instance $\{(1, \vec{a}), (2, \vec{b})\}$, it outputs the d-th integer in the sequence $a_1, b_{a_1}, a_{b_{a_1}} \ldots$ with constant probability.

The sample complexity of $\mathrm{PC}(d, \ell)$ under local privacy must scale at least linearly with ℓ.

[3] At a high level, each user sends a random number of $\mathbf{Ber}(1/2)$ messages. The aggregate number of such bits is guaranteed to be $\Theta(\frac{1}{\varepsilon^2} \log \frac{1}{\delta})$ with $1 - \delta$ probability.

Theorem 17 (Joseph et al. [38]). *If an (ε, δ)-locally private protocol solves* $\mathrm{PC}(2, \ell)$ *with sample complexity n then $n = \Omega(\ell)$.*

In stark contrast, the sample complexity under shuffle privacy is *independent of* ℓ:

Theorem 18 (Balcer & Cheu [6]). *There is a $8 \cdot (\ell!)^2$-message protocol that satisfies $(2 \cdot \varepsilon/\sqrt{\gamma}, 2\delta)$-robust shuffle privacy and solves* $\mathrm{PC}(2, \ell)$ *with sample complexity $O(\frac{1}{\varepsilon^2} \log \frac{1}{\delta})$.*

Proof. Let $\pi(\ell)$ denote all permutations of $[\ell]$. Observe that the tuples $(1, \vec{a}), (2, \vec{b})$ are elements of the universe $\{1, 2\} \times \pi(\ell)$ which has size $2 \cdot \ell!$. We can solve the problem once we have a protocol that singles out $(1, \vec{a})$ and $(2, \vec{b})$ from the universe with constant probability.

Balcer & Cheu argue that the task of privately identifying $(1, \vec{a})$ and $(2, \vec{b})$ with constant probability is $O(\frac{1}{\varepsilon^2} \log \frac{1}{\delta})$. By a straightforward concentration argument, it suffices to have $O(t)$ samples to ensure $(1, \vec{a})$ and $(2, \vec{b})$ each appear $\geq t + 1$ times with constant probability. Taking universe size $k = 4 \cdot (\ell!)^2$, we then use the histogram protocol built atop ZSUM (Theorem 12). When $t = \Omega(\frac{1}{\varepsilon^2} \log \frac{1}{\delta})$, it will report nonzero frequencies for $(1, \vec{a})$ and $(2, \vec{b})$ but zero for every other element in the universe. □

4 Separations between Central & Shuffle Privacy

There are known separations between the (one-round) shuffle model and the central model. The proofs thus far require some natural structural constraint.

4.1 Single-message Shuffle Privacy

The first class of lower bounds hold for protocols wherein each user sends exactly one message with probability 1.[4] We begin with a negative result for bounded-value sums proved by Balle, Bell, Gascón, and Nissim [10].

Theorem 19 (Balle et al. [10]). *If a single-message shuffle protocol satisfies (ε, δ) differential privacy for n users and computes bounded-value sums, then the mean-squared error must be $\Omega(n^{1/3})$.*

In contrast, the centrally private Laplace mechanism achieves mean-squared error of $O(1/\varepsilon^2)$.

The techniques used to prove the above are specific to bounded-value sums. A more general technique is to study what happens when we remove the shuffler from a single-message protocol. This takes us to what we can call *removal lemmas*

Lemma 20 (Balcer & Cheu [6]). *If a single-message protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ satisfies pure shuffle privacy, then removing the shuffler leaves behind a pure locally private protocol. Specifically, $\mathcal{R}$ must satisfy ε-differential privacy on its own whenever the shuffle protocol as a whole is ε-private.*

This means that under pure differential privacy, the single-message shuffle model is *exactly equivalent* to the local model. So all separations between the central and local models hold here as well.

But it is clear from RR that this exact equivalence does not hold for approximate shuffle privacy. The following removal lemma accommodates the relaxation.

Lemma 21 (Cheu et al. [22]). *If a single-message protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ satisfies (ε, δ)-shuffle privacy for n users, then $\mathcal{R}$ must satisfy $(\varepsilon + \ln n, \delta)$-differential privacy on its own.*

[4] The lower bounds also hold in the case where users send *at most* one message. This is proven by a simple transformation: send a dummy symbol $\perp$ to denote the no-message event.

Thus, we can invoke any local model lower bound that holds for $(\varepsilon + \ln n, \delta)$ privacy. As an example, the recipe implies the following lower bound on the error of histograms.

Theorem 22 (Ghazi et al. [32])**.** *Any single-message protocol that satisfies $(1, o(1/n))$-shuffle privacy and outputs histograms with ℓ_∞ error $n/10$ must have $n = \Omega(\frac{\log k}{\log\log k})$.*

In contrast, there is a central model algorithm where $n = O(1)$ suffices for the same privacy and accuracy regimes.

4.2 m-message Shuffle Privacy

A natural idea is to somehow extend the removal lemma from the single-message case to the m-message case. But notice that an adversary can recover the input of $\mathcal{R}_{\mathsf{ZSUM}}$ in the clear by simply looking at the first bit of the output. Meanwhile, the protocol $\mathcal{P}_{\mathsf{ZSUM}}$ as a whole is differentially private.

Despite this hurdle, two works manage to prove lower bounds for m-message protocols. These lower bounds make the simplifying assumption that the local randomizer sorts (or shuffles) its output messages before giving them to the shuffler. This does not affect accuracy or privacy because the local sorting (or local shuffling) is undone by the shuffler anyway.

4.2.1 Approach 1

One paper by Beimel, Haitner, Nissim, and Stemmer [13] obtains a bound on the mutual information between the output of an m-message randomizer and uniformly random input.

Lemma 23. *Let $\mathcal{P} = (\mathcal{R}, \mathcal{A})$[5] be an m-message (ε, δ)-shuffle private protocol and let $Z_1, \ldots, Z_n \in \mathcal{X}$ be (possibly correlated) random variables. In the execution of $\mathcal{P}$ on input $Z_1, \ldots, Z_n$, let Y_i be the (sorted) output of the i-th user and let W denote the public randomness. For any $i \in [n]$, if Z_i is uniformly random over $\mathcal{X}$, then*

$$I(Y_i, W; Z_i) = O\left((en)^m \cdot \left(\varepsilon^2 + \frac{\delta}{\varepsilon}\log|\mathcal{X}| + \frac{\delta}{\varepsilon}\log\frac{\varepsilon}{\delta}\right) + m\log n\right).$$

Proof Sketch. Given (ε, δ)-shuffle private protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$, we can create a (ε, δ)-locally private randomizer $\mathcal{R}_{\mathcal{P}}$: on input x, W, obtain nm messages by executing $(\mathcal{S} \circ \mathcal{R}^n)(U_1, U_2, \ldots, U_{n-1}, x)$ where U_i is uniformly random, and then output a random (sorted) subset of m messages. Privacy follows from post-processing.

Now let $Y_i' \leftarrow \mathcal{R}_{\mathcal{P}}(Z_i, W)$. Prior work has shown that $I(Y_i', W; Z_i) = O(\varepsilon^2 + \frac{\delta}{\varepsilon}\log|\mathcal{X}| + \frac{\delta}{\varepsilon}\log\frac{\varepsilon}{\delta})$. Then we use the fact that Y_i' coincides with Y_i with probability $\binom{nm}{m}^{-1}$. □

The above lemma is then used to obtain a lower bound for the *common element* problem. Refer to [13] for the full details.

4.2.2 Approach 2

A paper by Chen, Ghazi, Kumar, and Manurangsi [18] takes a different approach. They define a relaxation of differentially private algorithms—called *dominated algorithms*— and then argue that the local randomizer of a shuffle private protocol satisfies that definition.

Definition 24 (Chen et al. [18])**.** An algorithm $\mathcal{R} : \mathcal{X} \times \{0,1\}^* \to \mathcal{Y}$ is (ε, δ)-dominated if there exists a distribution $\mathbf{D}$ such that for all $x \in \mathcal{X}$, all $w \in \{0,1\}^r$, and all $Y \in \mathcal{Y}$, $\mathbb{P}[\mathcal{R}(x, w) \in Y] \leq e^\varepsilon \cdot \mathbb{P}[\mathbf{D} \in Y] + \delta$

Notice that the above definition is a one-sided variant of differential privacy. We do not require the probability mass function of $\mathcal{R}(x, w)$ to dominate that of $\mathbf{D}$.

[5] The original statement allows for different users to run different randomizers, but we omit that degree of freedom for simplicity

Lemma 25. *If $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ is an m-message (ε, δ)-shuffle private protocol, then $\mathcal{R}$ is $(\varepsilon + m\ln(en), \delta)$-dominated.*

Using the above, Chen et al. derive a lower bound for parity learning:

Theorem 26. *If $\mathcal{P}$ is a m-message shuffle protocol that solves d-dimensional parity learning, then its sample complexity is $\Omega(2^{d/(m+1)})$.*

In contrast, Kasiviswanathan, Lee, Nissim, Raskhodnikova, and Smith [39] show that centrally private parity learning is possible with just $O(d)$ samples.

4.3 Robust Shuffle Privacy

The third class of lower bound applies to robustly shuffle private protocols. To obtain these results, we again develop reductions, but this time to the online model. Briefly, an online algorithm receives user data one at a time and updates its internal state upon reading each input. The algorithm produces output when the stream ends.

How do we define privacy in the online model? Dwork, Naor, Pitassi, Rothblum, and Yekhanin [27] propose *pan-privacy*: for any time t, the joint distribution of the internal state at time t and the output should be differentially private. This models one-time violations of the algorithm's integrity (i.e. a hack, a subpoena, or a change in ownership). Balcer, Cheu, Joseph, and Mao [7] describe a generic transformation from robust shuffle privacy to pan-privacy that preserves accuracy for many statistical problems. Thus, existing lower bounds that hold under pan-privacy—for the distinct elements and uniformity testing problems—carry over to robust shuffle privacy. Cheu & Ullman [23] and Nissim & Yan [40] obtain new lower bounds for pan-private selection and parity learning, which again implies lower bounds for robust shuffle privacy. This second batch of results imply exponentially large separations in sample complexity between robust shuffle privacy and central privacy.

In the thesis by Cheu [19], the recipe is somewhat simplified. The key observation is that all known lower bounds for pan-privacy only require the privacy of the internal state and not that of the state-output pair. [19] uses *internal privacy* to refer to this weaker notion. Transforming robustly shuffle private protocols to internally private algorithms is a little easier than transforming them to pan-private algorithms, while still producing the same results.[6]

In the following lemma, $\mathbf{U}$ is any distribution[7] over the data universe $\mathcal{X}$ and let $\mathbf{U}^n$ be the corresponding product distribution over $\mathcal{X}^n$. For any other distribution $\mathbf{D}$, let $\mathbf{D}_{(p)}$ be the mixture $p \cdot \mathbf{D} + (1-p) \cdot \mathbf{U}$.

Lemma 27 (Balcer et al. [7], Cheu [19])**.** *Let $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ be an $(\tilde{\varepsilon}, \tilde{\delta})$-robustly shuffle private protocol. There is an $(\tilde{\varepsilon}(1/2), \tilde{\delta}(1/2))$-internally private algorithm $\mathcal{Q}_{\mathcal{P}}$ such that*

$$d_{\mathrm{TV}}(\mathcal{Q}_{\mathcal{P}}(\mathbf{U}^{n/2}), \mathcal{P}(\mathbf{U}^n)) = 0 \tag{2}$$

and, for any distribution $\mathbf{D}$ over $\mathcal{X}$,

$$d_{\mathrm{TV}}(\mathcal{Q}_{\mathcal{P}}(\mathbf{D}^{n/2}), \mathcal{P}(\mathbf{D}^n_{(1/4)})) < 1/6. \tag{3}$$

Proof Sketch. The online algorithm's initial internal state will be the output of $(\mathcal{S} \circ \mathcal{R}^{n/2})$ run on $n/2$ i.i.d. samples from $\mathbf{U}$. Each time a user's data point is read, the algorithm will execute $\mathcal{R}$ on it and add the messages to the internal state (inserted in some random position). This ensures internal privacy because any internal state is equivalent to the output of the shuffler when the protocol is run on (at least) $n/2$ data points.

The output of $\mathcal{Q}_{\mathcal{P}}$ is simply the execution of $\mathcal{A}$ on the final state. (2) is immediate from the construction. To obtain (3), we begin with the observation that the final internal state consists of messages produced

[6] It also avoids a technical limitation of the original transformation, which is that $\tilde{\varepsilon}$ needs to be defined at $\gamma = 1/3$.

[7] As the symbol suggests, it is typically the uniform distribution

Table 2: Comparison of impossibility results for robust shuffle privacy with centrally private algorithms. d and α are dimension and error parameters, respectively. k is the number of inputs to the learned parity function. For simplicity, we use $\varepsilon = \hat{\varepsilon}(1/2)$ and $\delta = \hat{\delta}(1/2)$. $*$ indicates that $\delta \log(\binom{d}{\leq k}/\delta) \ll \alpha^2\varepsilon^2/\binom{d}{\leq k}$.

		Robust Shuffle Privacy	Central Privacy
Additive Error of	Distinct Elements	$\Omega\left(\sqrt{\frac{d}{\varepsilon}} + \frac{1}{\varepsilon}\right)$	$O\left(\frac{1}{\varepsilon}\right)$
		[7] ($n \geq 2d$)	[26] (Laplace mech.)
Sample Complexity of	Uniformity Testing	$\Omega\left(\frac{d^{2/3}}{\alpha^{4/3}\varepsilon^{2/3}} + \frac{\sqrt{d}}{\alpha^2} + \frac{1}{\alpha\varepsilon}\right)$	$O\left(\frac{\sqrt{d}}{\alpha^2} + \frac{\sqrt{d}}{\alpha\varepsilon} + \frac{d^{1/3}}{\alpha^{4/3}\varepsilon^{2/3}} + \frac{1}{\alpha\varepsilon}\right)$
		[7] ($\delta = 0$)	[4]
	Parity Learning	$\Omega\left(\sqrt{\binom{d}{\leq k}/\alpha\varepsilon}\right)$	$O(\log\binom{d}{\leq k})$
		[23] agnostic, [40] realizable $*$	[39]

by running the protocol on independent samples from $\mathbf{U}, \ldots, \mathbf{U}, \mathbf{D}, \ldots, \mathbf{D}$. This looks almost like $\mathbf{D}_{(1/2)}$ except that the number of samples from $\mathbf{D}$ should be binomial. We correct this by slightly modifying the transformation: replace the first $\mathbf{Bin}(n/2, q)$ user data with samples from $\mathbf{U}$. q is chosen so that the shuffled set of samples approximates samples from $\mathbf{D}_{(1/4)}$. The modification does not invalidate our preceding arguments. □

5 The Promise of Interactivity

Thus far, we have limited our attention to one-round shuffle protocols. We shall now explore what shuffle protocols can do with multiple rounds of communication and how they stack up against centrally private algorithms.

5.1 Sequential Interactivity (S.I.)

To start, it will help to understand sequentially interactive local protocols. Here, each user sends only one message but the randomizer of user i can depend on the *transcript* generated by users $1, \ldots, i-1$. This is useful when implementing private iterative methods like gradient descent. Strong separations are known to exist between one-round and sequentially interactive local privacy. Joseph, Mao, and Roth [38] show that two rounds suffice to solve pointer-chasing $\mathrm{PC}(2, \ell)$ with sample complexity $O_\varepsilon(\log \ell)$. This is exponentially smaller than the lower bound of $\Omega_\varepsilon(\ell)$ in the one-round case (Theorem 17).

Given that S.I. provably enhances the local model, how can we adapt it to the shuffle model?

Approach 1. One option is to re-interpret the shuffler as an anonymity service: users are shuffled u.a.r. and then the analyzer deploys a sequentially interactive local protocol.[8] The recent amplification-by-shuffling lemma by Feldman, McMillan, and Talwar [30] holds in this version of the model. Notice that if the randomizer does not get updated over time, we are just running a one-round single-message shuffle protocol. Also observe that it is not possible to run multi-message protocols in this variant of the shuffle model, since the random permutation is limited to the users and not the messages.

[8] An equivalent interpretation is that, at the beginning of each round of the S.I. local protocol, a middle-man samples a random user without replacement.

Table 3: Comparison of positive results in the S.I. shuffle model with central model counterparts. For brevity, we suppress the term $\sum_{a\in[k]:\Delta_a>0} \frac{\log T}{\Delta_a}$ present in both MAB bounds and the term $1/\sqrt{n}$ in the SCO bounds. SCO bounds also omit logarithmic factors, as well as convexity and smoothness parameters.

		S.I. Shuffle Privacy	Central Privacy
Regret of	k-arm bandit	$O\left(\frac{k}{\varepsilon}\sqrt{\log\frac{1}{\delta}}\log T\right)$ [41]	$O(k/\varepsilon)$ [42]
SCO error	Convex, Non-Smooth	$O(d^{1/3}/\varepsilon^{2/3}n^{2/3})$	$O(\sqrt{d}/\varepsilon n)$ [12]
	Convex, Smooth	$O(d^{2/5}/\varepsilon^{4/5}n^{4/5})$	
	Strongly Convex, Non-Smooth	$O(d^{2/3}/\varepsilon^{4/3}n^{4/3})$	
	Strongly Convex, Smooth	$O(d/\varepsilon^2 n^2)$	

Approach 2. An alternative way to adapt S.I. is to simply run one-round shuffle protocols on disjoint batches of users. The i-th protocol can depend on the transcript from protocols $1,\ldots,i-1$ and can be multi-message. Summarized in Table 3, two recent works have described protocols in this model. Tenenbaum, Kaplan, Mansour, Stemmer [41] study the multi-arm bandit problem. The authors give cumulative regret bounds that match those of the central model up to logarithmic factors. Cheu, Joseph, Mao, and Peng [20] focus instead on the problem of stochastic convex optimization (SCO). They describe a one-round vector summation protocol that is repeatedly called inside gradient descent algorithms.

5.2 Full Interactivity (F.I.)

In fully interactive local protocols, a user can communicate with the analyzer multiple times. The transcript of all the user's messages must be differentially private.

We can adapt F.I. to the shuffle model in the following way: run one-round shuffle protocols on batches of users that are not necessarily disjoint. The transcript of a fully interactive shuffle protocol is the entire list of the outputs of the shuffler. As with local protocols, this transcript must be differentially private. As an example, Cheu et al. [20] give a SCO protocol that relies on this ability to query a user multiple times.

Beimel et al. [13] describe a very powerful transformation that shows fully interactive shuffle private protocols can be as powerful as centrally private ones(!)

Theorem 28. *Let $\mathcal{M}$ be an arbitrary (central model) randomized algorithm. Assuming an honest majority and semi-honest corruptions, there exists a two-round fully interactive shuffle protocol $\mathcal{P}_{\mathcal{M}}$ that simulates $\mathcal{M}$.*

Proof Sketch. The idea is to simulate an information-theoretically secure multi-party computation protocol by Applebaum, Brakersky, and Tsabary (ABT), the source of the honest majority requirement. The MPC protocol relies on secure channels of communication; to simulate these channels in the shuffle model, Beimel et al. use one-time pads.

We begin with a simple building block: Alice and Bob want to agree on one random bit, with one party designated as "leader." As usual, the adversary's view is limited to the output of the shuffler. Suppose both Alice and Bob each flip one fair coin and send their bits. By examining the output of the shuffler, each party can learn what the leader sampled.[9] However, if both have 0 or both have 1, the adversary learns both their bits. This has a 1/2 chance of occurring, so they repeat the process enough

[9] We can use the analyzer as a referee to relay the shuffler's output. Alternatively, we could model the shuffler as having the ability to broadcast its output (as done by Beimel et al.).

times to drive the probability down. Note that these repetitions can be done in parallel by labeling each bit with a repetition number. When there are $n > 2$ users, we label each message with the pair of users who will read them.

Naively combining the above key agreement with ABT leads to a three-round protocol (one for key agreement and two for ABT). Beimel et al. show how to use the leftover hash lemma to send a message and the pad at the same time, reducing the number of rounds to two. □

6 Open Questions

(When) Are one-round shuffle protocols intrinsically robust? The fact that each user is performing the same randomization algorithm implies an equal division of labor. So it seems like drop-outs should cause a graceful degradation of privacy. But this is not always the case: as detailed in Appendix B, there are multi-message protocols that satisfy shuffle privacy (finite ε and $\delta < 1$) when executed by n users but do not satisfy shuffle privacy for $n - 1$ users.

The single-message setting is a bit more promising. One can imagine an improved removal lemma (Section 4.1) that matches the local privacy regime covered by amplification-by-shuffling lemmas. That is, it might be possible to have a bound on the local privacy of a shuffle protocol's randomizer $\mathcal{R}$ which can be plugged into an amplification lemma (so that we can bound the shuffle privacy offered to γn honest users).

For uniformity testing, how can we close the gap between pure and approximate shuffle privacy? As it stands, there is a tester that satisfies approximate shuffle privacy and a lower bound for testers that satisfy pure shuffle privacy. The approach to testing sketched in this survey could use a different counting subroutine (such as the pure d.p. one by [31]), but the current analysis demands noise symmetry and unbiased estimators.

In both the central and local models, pure d.p. is not a stronger constraint on the sample complexity of a binary decision problem than approximate d.p. But is this the case for pan-privacy? Robust shuffle privacy?

What are the limits of S.I. protocols? It appears difficult to perform the same level of simulation as done in the fully interactive setting. There may be a way to adapt the strong lower bounds developed by Joseph et al. [38, 37]. Note that we can ask this question for both approaches of defining S.I. shuffle protocols.

How competitive is the shuffle model as compared to the secure aggregation model? Like the shuffle model, the secure aggregation model addresses the problem of an untrusted analyzer. Instead of a shuffler, there is a trusted service that performs modular arithmetic upon user messages. Ishai, Kushilevitz, Ostrovsky, and Sahai [36] describe a way to simulate the behavior of this primitive in the shuffle model. Conversely, it is not hard to see that a sufficiently large modulus enables simulation of any shuffle protocol. So there is an equivalence between the models. However, it may be loose: a (shuffle/sec.agg.) protocol is mapped to *some* (sec.agg./shuffle) protocol for the same problem with the same accuracy but with potentially worse communication complexity than is actually needed.

A Reducing the Cost of Transmission

In any real implementation of a shuffle protocol, users will have to transmit their messages across a network. The two critical metrics are the number of messages sent by each user and the total number of bits they consume. We use *message complexity* to refer to the former and the more typical *communication complexity* to refer to the latter. In this Appendix, we give an overview of protocols that are designed to minimize one or both of these quantities.

A.1 Bounded-value Sums

In this setting, users have values in the interval $[0, 1]$ and the objective is to privately compute their sum. As previously stated, it is possible to rely on a binary sum protocol: a fixed-point representation can transform a continuous value into a set of zeroes and ones, upon which we perform the local ranomization. A longer fixed-point representation reduces the rounding error, but increases the noise needed for privacy; two works [22, 20] show that $\sqrt{n}$ is an optimum choice.

The downside of the above approach is that the message complexity —and thus the communication complexity— scales with $\sqrt{n}$. To rectify this, Balle et al. [8, 9] and Ghazi et al. [35, 34] use a different reduction that leads to a logarithmic communication complexity.

Theorem 29. *There is an (ε, δ)-shuffle private protocol for bounded-value sums with error $O(\frac{1}{\varepsilon})$ where each user sends $O(\frac{\log(1/\delta)}{\log(n)})$ messages, each consisting of $O(\log n)$ bits.*

Proof Sketch. At a high level, the goal is to simulate the symmetric geometric distribution $\mathbf{SG}(\varepsilon)$, also known as the discrete Laplace distribution. In the central model, adding such noise suffices for pure differential privacy.

The first step is to equate a sample from the $\mathbf{SG}(\varepsilon)$ with the sum of n samples from another distribution $\mathbf{D}_\varepsilon$. This property is called *infinite divisibility*, most obvious in the Gaussian distribution. The next step is to recall a modular arithmetic protocol $\mathcal{P}_{\mathsf{MOD}} = (\mathcal{R}_{\mathsf{MOD}}, \mathcal{A}_{\mathsf{MOD}})$ by Ishai, Kushilevitz, Ostrovsky, and Sahai [36]. It is not differentially private but it does have the following security property: two input datasets with the same sum (mod q) cause the protocol to produce a shuffled set of messages that are δ-close in statistical distance. Finally, we define $\mathcal{R}$ to be the execution of $\mathcal{R}_{\mathsf{MOD}}$ on $y_i \leftarrow x_i + \eta$ where $\eta \sim \mathbf{D}_\varepsilon$.

If an adversary can only recover $\sum y_i$, then we will have ε-differential privacy. And due to the way we use MOD, the output of the shuffler $(\mathcal{S} \circ \mathcal{R}^n)(x_1, \ldots, x_n)$ is δ-close to $(\mathcal{S} \circ \mathcal{R}^n_{\mathsf{MOD}})(\sum y_i, 0, \ldots, 0)$. This is enough to ensure approximate differential privacy. The error bound $O(\frac{1}{\varepsilon})$ follows from the fact that we are simulating the geometric mechanism, as well as the fact that sums exceed the modulus with very low probability.

Refer to Balle et al. [9] and Ghazi et al. [34] for analyses of the message complexity of MOD. □

A.2 Improving Balcer & Cheu's histogram protocol using hashing

Here, we return to the histogram protocol found in [6]. For any integer constant $T > 1$, we will show how to change the number of messages sent by each user from $\Theta(k)$ to $\Theta(n \cdot k^{1/T})$. The argument comes from discussion with Kobbi Nissim and Rasmus Pagh. Recall that $c_j(\vec{x})$ denotes the count of j in the dataset $\vec{x}$.

Let $\hat{k}$ be an arbitrary integer for now. Public randomness chooses T uniformly random hash functions $\{h^{(t)} : [k] \to [\hat{k}]\}_{\forall t \in [T]}$. Each user i loops through $t \in [T]$: compute the hash $x_i^{(t)} \leftarrow h^{(t)}(x_i)$ and then run the histogram randomizer (for universe $[\hat{k}]$) on $x_i^{(t)}$. The shuffler therefore receives $T \cdot 2\hat{k}$ messages from each user. By basic composition, the privacy parameters degrade by only a factor of T. So we rescale ε and δ by T to find that we have maximum error $\alpha = O(\frac{T^2}{\varepsilon^2} \log \frac{T}{\delta})$ with constant probability.

Now we show how the analyzer recovers an approximate histogram for $\vec{x}$. We first define $\vec{x}^{(t)}$ to be the vector of hashes $x_1^{(t)}, \ldots, x_1^{(t)}$ produced by running $h^{(t)}$ on the data $x_1, \ldots, x_n$. Using the messages received by the shuffler, the analyzer will obtain T approximate histograms $\{(\tilde{c}_1^{(t)}, \ldots, \tilde{c}_{\hat{k}}^{(t)}\}_{t \in [T]}$, where $\tilde{c}_{\hat{j}}^{(t)}$ is an estimate of $c_{\hat{j}}(\vec{x}^{(t)})$. Then, for each $j \in [k]$, reports the minimum of $\tilde{c}_{h^{(t)}(j)}^{(t)}$.

To bound the error of this estimate of $c_j(\vec{x})$, we define E_j to denote the event where there is some t such that, for every $j' \in \vec{x} - \{j\}$, $h^{(t)}(j) \neq h^{(t)}(j')$. When this event occurs, $c_{h^{(t)}(j)}(\vec{x}^{(t)})$ is exactly $c_j(\vec{x})$. If there is another t' where this condition does not hold, $c_{h^{(t')}(j)}(\vec{x}^{(t')})$ is an *over*estimate of $c_j(\vec{x})$. Thus, the minimum of $c_{h^{(t)}(j)}(\vec{x}^{(t)})$ is exactly the count of j in $\vec{x}$ when E_j occurs. Given that the analyzer can obtain estimates of these counts with error at most α, the minimum of the estimates can only be wrong by α.

It is straightforward to see that $\mathbb{P}\left[\neg E_j\right] = \mathbb{P}\left[\forall t \in [T]\ \exists j' \in \vec{x}\ h_t(j') = h_t(j)\right] \leq (n/\hat{k})^T$. By a union bound, the probability that *any* E_j fails to occur is $\leq k \cdot (n/\hat{k})^T$. If $\hat{k} = n \cdot (100k)^{1/T}$, this failure probability is at most $1/100$.

A.3 Histograms & Range queries

In Table 4, we place the enhanced version of Balcer & Cheu's protocol alongside the protocols by Ghazi et al [32]. The communication complexity has only a logarithmic dependence on n, k. They use the count-min and Hadamard response techniques that found success in the local model.

The table presents two other histogram protocols. The first uses the same repeated counting template that we used in Section 3.2, but now with the binary sum protocol presented by Ghazi, Kumar, Manurangsi, and Pagh. The expected message complexity of this protocol vanishes with n, so that a large userbase counteracts a large dimension k. The second also has a vanishing message complexity, but with a faster rate. Each user in this protocol by Cheu and Zhilyaev [24] randomize the one-hot encoding of their data, as well as a small number of $(0, \ldots, 0)$ strings. These fake users contribute just enough cover noise to protect real users.

[32] also explain how to use their protocols in a black-box way to solve the range-query problem. In this setting, data is drawn from $[k]^d$ and the objective is to estimate the number of points in a given rectangle. Refer to Table 5 for a summary of the results.

A.4 Lower Bounds

We close this appendix with a result by Ghazi et al. [31] which states that every communication-bounded shuffle protocol must imply some local protocol with a nontrivial privacy guarantee:

Lemma 30 (Ghazi et al. [31])**.** *Suppose $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ satisfies $O(1)$-shuffle privacy and each user sends m messages of ℓ bits. Then the local randomizer $(\mathcal{S} \circ \mathcal{R}^1)$ satisfies $(0, 1 - 2^{-O(m^2\ell)})$-differential privacy.*

Table 4: Shuffle protocols for histograms. All take $\delta > 0$. We assume $\delta < 1/\log k$ for results from [32] and $\delta \geq e^{-O(n\varepsilon^2)}$ for the result from [6]. T is a positive integer constant. The notation $\tilde{O}(\dots)$ suppresses nested logarithms.

Technique	Error	Messages per User	Bits per Message	Source
ZSUM+hashing	$O\left(\frac{T^2}{\varepsilon^2}\log\frac{T}{\delta}\right)$	$O(n \cdot k^{1/T})$	$O(\log nk)$	[6]
Count-Min	$\tilde{O}\left(\frac{1}{\varepsilon}\sqrt{\log^3 k \log\frac{1}{\delta}}\right)$	$\tilde{O}\left(\frac{1}{\varepsilon^2}\log^3 k \log\frac{1}{\delta}\right)$	$O(\log n + \log\log k)$	[32]
Hadamard	$O\left(\log k + \frac{1}{\varepsilon}\sqrt{\log k \log\frac{1}{\varepsilon\delta}}\right)$	$O\left(\frac{1}{\varepsilon^2}\log\frac{1}{\varepsilon\delta}\right)$	$O(\log n \log k)$	[32]
Correlated Noise	$O(\frac{1}{\varepsilon}\log k)$	$1 + O(\frac{k}{\varepsilon^2 n}\log^2\frac{1}{\delta})$	$O(\log k)$	[33]
Fake Users	$O(\log k + \frac{1}{\varepsilon}\sqrt{\log k \log\frac{1}{\delta}})$	$1 + O(\frac{\log k}{n} + \frac{1}{\varepsilon^2 n}\log\frac{1}{\delta})$	k	[24]

Table 5: Shuffle protocols for range queries. All take $\delta > 0$. $n \leq k^d$ for neatness

Technique	Error	Messages per User	Bits per Message
Count-Min	$O(\frac{1}{\varepsilon}\log^{2d+3/2}(k^d)\log\frac{1}{\delta})$	$O(\frac{1}{\varepsilon^2}\log^{3d+3}(k^d)\log\frac{1}{\delta})$	$O(\log n + \log(d\log k))$
Hadamard	$O(\frac{1}{\varepsilon}\log^{2d+1/2}(k^d)\log\frac{1}{\varepsilon\delta})$	$O(\frac{1}{\varepsilon^2}\log^{2d}(k^d)\log\frac{1}{\varepsilon\delta})$	$O(\log(n)\cdot d\log k)$

By way of the local model, this implies a lower bound for binary sums:

Corollary 31 (Ghazi et al. [31])**.** *If an m-message shuffle protocol satisfies $O(1)$-differential privacy and computes binary sums up to error $o(\sqrt{n})$, then $m^2\ell = \Omega(\log n)$.*

B Shuffle Protocols with Brittle Privacy

Here, we describe two protocols which satisfy non-trivial shuffle privacy but are not robust to a single drop-out.

Theorem 32. *There exists a protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ such that $(\mathcal{S}\circ\mathcal{R}^n)$ satisfies pure differential privacy but $(\mathcal{S}\circ\mathcal{R}^{n-1})$* does not *satisfy pure differential privacy.*

Proof. Define $\mathcal{R} : \{0,1\} \to \{1\}^*$ such that the length of the output (number of messages) is uniformly random over $\{0,\dots,n+2\}$ on input 0 and uniformly random over $\{0,1,n+1,n+2\}$ on input 1.

We first show that $(\mathcal{S}\circ\mathcal{R}^n)$ is ε-differentially private for a finite value of ε. This is achieved by arguing that, for every input $\vec{x}$, the length of $(\mathcal{S}\circ\mathcal{R}^n)(\vec{x})$ has support $G = \{0,\dots,n^2+2n\}$. We use the notation $\mathrm{supp}(|(\mathcal{S}\circ\mathcal{R}^n)(\vec{x})|) = G$. This equivalence holds if and only if the two following statements are true: (i) the length of $(\mathcal{S}\circ\mathcal{R}^n)(\vec{x})$ must be some member of the set $G := \{0,\dots,n^2+2n\}$ and (ii) each integer in G has a nonzero probability of being the length.

(i) is immediate from the specification of $\mathcal{R}$: the length is maximized when all users send $n+2$ messages and minimized when they send no messages. To prove (ii), we perform case analysis over $\vec{x}$.

When $\vec{x} = 0^n$, we shall use induction over the elements of G in order. The base case is immediate: $\mathbb{P}[|(\mathcal{S}\circ\mathcal{R}^n)(0^n)| = 0] = \mathbb{P}[|\mathcal{R}(0)| = 0]^n > 0$. For the inductive step, we are given that $\mathbb{P}[|(\mathcal{S}\circ\mathcal{R}^n)(0^n)| = g] >$

0 for some $g \in G - \{n^2 + 2n\}$ and we show that $\mathbb{P}[|(\mathcal{S} \circ \mathcal{R}^n)(0^n)| = g + 1] > 0$. There must be a vector $\vec{g} \in \{0, \ldots, n+2\}^n$ such that $\sum g_i = g$ and $\prod_{j=1}^{n} \mathbb{P}\left[|\mathcal{R}(0)| = g_j\right] > 0$. Because $g < n^2 + 2n$, there must be some index i such that $g_i < n + 2$. Hence, define $\vec{g}'$ such that $g'_i = g_i + 1$ and $g'_j = g_j$ for all $j \neq i$. Now we have that $\mathbb{P}[|(\mathcal{S} \circ \mathcal{R}^n)(0^n)| = g + 1] \geq \prod_{j=1}^{n} \mathbb{P}\left[|\mathcal{R}(0)| = g'_j\right] > 0$.

When $\vec{x} = 1^n$, the proof is similar except the inductive step proceeds via case analysis. If $0 \in \vec{g}$, we simply create $\vec{g}'$ by changing the 0 to 1. If $n + 1 \in \vec{g}$ we create $\vec{g}'$ by changing the $n + 1$ to $n + 2$. Otherwise, there is some integer $k \geq 0$ such that $\vec{g}$ consists of k copies of $(n + 2)$ and $n - k$ copies of 1. In this case, we construct $\vec{g}'$ which has $n - k - 1$ copies of 0 and $k + 1$ copies of $n + 1$. In all cases, $\sum g'_j = 1 + \sum g_j$ and $\prod \mathbb{P}\left[\mathcal{R}(1) = g'_j\right] > 0$.

For any other choice of $\vec{x}$, the fact that $\text{supp}(|\mathcal{R}(1)|) \subset \text{supp}(|\mathcal{R}(0)|)$ implies

$$\text{supp}(|(\mathcal{S} \circ \mathcal{R}^n)(1^n)|) \subseteq \text{supp}(|(\mathcal{S} \circ \mathcal{R}^n)(\vec{x})|) \subseteq \text{supp}(|(\mathcal{S} \circ \mathcal{R}^n)(0^n)|)$$

so that all the supports are precisely G.

Now we show that $(\mathcal{S} \circ \mathcal{R}^{n-1})$ cannot satisfy pure differential privacy. Consider the neighboring inputs $\vec{x} := 0^{n-1}$ and $\vec{x}' := 0^{n-2}1$. There is a non-zero probability that $(\mathcal{S} \circ \mathcal{R}^{n-1})(\vec{x})$ has length n. However, this is impossible when the input is $\vec{x}'$, so the likelihood ratio is unbounded. □

Theorem 33. *There exists a protocol $\mathcal{P} = (\mathcal{R}, \mathcal{A})$ such that $(\mathcal{S} \circ \mathcal{R}^n)$ satisfies approximate differential privacy, but $(\mathcal{S} \circ \mathcal{R}^{n-1})$ does not satisfy* any *differential privacy.*

Proof. Define $\mathcal{R} : \{0, 1\} \to \{1\}^*$ such that the length of the output is uniform over $\{0, 1\}$ on input 0 and uniform over $\{n, n + 1\}$ on input 1.

We first show that $(\mathcal{S} \circ \mathcal{R}^n)$ is (ε, δ)-differentially private for a finite value of ε and $\delta < 1$. This is achieved by arguing that, for any neighboring $\vec{x} \sim \vec{x}'$, the support of $(\mathcal{S} \circ \mathcal{R}^n)(\vec{x})$ intersects with that of $(\mathcal{S} \circ \mathcal{R}^n)(\vec{x}')$. Let k be the number of times 0 occurs in $\vec{x}$; without loss of generality, assume that the number of times 0 occurs in $\vec{x}'$ is $k + 1$. We have that

$$\begin{aligned}
&\mathbb{P}\left[|(\mathcal{S} \circ \mathcal{R}^n)(\vec{x})| = n^2 - kn\right] \\
&\geq \mathbb{P}\left[|(\mathcal{S} \circ \mathcal{R}^k)(0^k)| = 0\right] \cdot \mathbb{P}\left[|(\mathcal{S} \circ \mathcal{R}^{n-k})(1^{n-k})| = (n-k) \cdot n\right] \\
&> 0
\end{aligned}$$

and that

$$\begin{aligned}
&\mathbb{P}\left[|(\mathcal{S} \circ \mathcal{R}^n)(\vec{x}')| = n^2 - kn\right] \\
&\geq \mathbb{P}\left[|(\mathcal{S} \circ \mathcal{R}^k)(0^k)| = k\right] \cdot \mathbb{P}\left[|\mathcal{R}(0)| = 1\right] \cdot \mathbb{P}\left[|(\mathcal{S} \circ \mathcal{R}^{n-k-1})(1^{n-k-1})| = (n-k-1) \cdot (n+1)\right] \\
&> 0
\end{aligned}$$

Now we argue that $(\mathcal{S} \circ \mathcal{R}^{n-1})$ cannot satisfy any degree of differential privacy. Given $\vec{x} = 0^{n-1}$ and $\vec{x}' = 0^{n-2}, 1$, the maximum length of $(\mathcal{S} \circ \mathcal{R}^{n-1})(\vec{x})$ is $n - 1$ while the minimum length of $(\mathcal{S} \circ \mathcal{R}^{n-1})(\vec{x}')$ is n. Hence, we have neighboring inputs but the supports of the induced distributions are disjoint. □
